

The Complete Treatise on the Zero Inflation Risk Premium

Asset Pricing, Inflation, and Macroeconomic Stability

Soumadeep Ghosh

Kolkata, India

Abstract

We present a comprehensive, mathematically rigorous framework that unifies a sequence of contributions across asset pricing, inflation theory, labour economics, and macroeconomic stability policy. The central observation is that the inflation risk premium can be identically zero at all points in time when specific functional forms govern asset returns, the risk-free rate, and expected inflation. Starting from a stochastic-discount-factor decomposition of nominal and real pricing kernels, we derive precise conditions under which the inflation risk premium vanishes, then construct a continuous-time example satisfying those conditions. Within this environment we establish a continuum of Capital Asset Pricing Model (CAPM) equilibria—including counterintuitive solutions with positive Jensen alpha and negative beta—and derive the bank rate under mean-reverting stochastic conditions via Itô calculus. A parallel labour-economics strand develops an equilibrium labour-fraction formula that couples the labour–leisure allocation to financial market parameters. We provide a rigorous definition of deflation as the positive magnitude of negative inflation, characterise exactly when deflation arises in our framework, and synthesise fiscal, monetary, and trade-policy conditions that prevent tariff-induced deflation in an open economy. Throughout, we connect the theoretical constructs to modern data-science and machine-learning methods: maximum-likelihood estimation of model parameters, Gaussian-process regression for inflation dynamics, neural-network estimation of time-varying beta, and reinforcement-learning design of optimal anti-deflation policy.

The treatise ends with “The End”

1 Introduction

A central question in financial economics is whether investors demand a positive *inflation risk premium*—extra expected return above the risk-free rate and expected inflation—to compensate for the co-movement of their portfolio with unanticipated inflation. Traditional asset-pricing theory, grounded in the stochastic discount factor (SDF) framework of Breeden [14] and Cochrane [13], presumes this premium is generically non-zero when inflation is stochastic and nominal payoffs are not perfectly indexed. Yet there is no logical necessity for the premium to be positive: it is zero whenever inflation risk is either perfectly predictable or fully spanned and hedged by traded assets.

The present treatise builds upon a sequence of ten independent papers by Ghosh [1, 2, 3, 4, 5, 6, 7, 8, 9, 10] to establish a unified mathematical framework in which:

- (i) the inflation risk premium is identically zero at every point in time;
- (ii) inflation, the risk-free rate, and asset returns satisfy explicit, closed-form functional forms;
- (iii) a continuum of CAPM equilibria coexist, with five concrete solutions tabulated;
- (iv) non-standard CAPM solutions with positive alpha and negative beta are exhibited and economically interpreted;
- (v) the bank rate evolves as the sum of a deterministic zero-IRP baseline and a mean-reverting Itô process sensitive to asset returns;
- (vi) the labour–leisure allocation is governed by a discounting equation connecting financial-market parameters to working hours;
- (vii) deflation is correctly distinguished from negative inflation and its occurrence is precisely characterised; and
- (viii) foreign-tariff-induced deflation is preventable through coordinated fiscal, monetary, and trade policy.

The contribution is theoretical and constructive. We do not argue that the world is exactly of this form; rather, the zero-IRP setting provides a transparent, internally consistent laboratory in which the mechanics of inflation-neutral asset pricing and macroeconomic stability can be studied in closed form. All model parameters are amenable to machine-learning estimation, as developed in Section 10.

Section 2 fixes notation. Section 3 defines the IRP rigorously via the SDF and derives general conditions for its vanishing. Section 4 constructs the explicit continuous-time example. Section 5 embeds the example into the CAPM. Section 6 analyses positive-alpha, negative-beta solutions. Section 7 derives the stochastic bank rate. Section 8 develops the mathematics of labour. Section 9 treats deflation definition, occurrence, and tariff-induced prevention. Section 10 connects all strands to data-science and machine-learning methods. Section 11 concludes.

2 Notation and Mathematical Preliminaries

Throughout, we work on a complete filtered probability space $(\Omega, \mathcal{F}, (\mathcal{F}_t)_{t \geq 0}, \mathbb{P})$ satisfying the usual right-continuity conditions. We write $\mathbb{E}_t[\cdot] := \mathbb{E}[\cdot \mid \mathcal{F}_t]$ for the conditional expectation at time t . The process $(W_t)_{t \geq 0}$ is a standard $\mathbb{P}$ -Brownian motion adapted to $(\mathcal{F}_t)$. The Itô differential satisfies $(dW_t)^2 = dt$, and the quadratic variation of a continuous semimartingale X is denoted $\langle X \rangle_t$. Itô’s formula for $f \in C^{1,2}(\mathbb{R}_{\geq 0} \times \mathbb{R})$ states

$$df(t, X_t) = \frac{\partial f}{\partial t} dt + f'(t, X_t) dX_t + \frac{1}{2} f''(t, X_t) d\langle X \rangle_t, \quad (1)$$

where primes denote spatial derivatives [18].

Table 1 collects the principal symbols used throughout the paper.

The following space was deliberately left blank.

Table 1: Principal notation, parameters, and their domains.

Symbol	Description	Domain
t	Continuous time	$\mathbb{R}$
$r_A(t)$	Instantaneous expected nominal return on asset A	$\mathbb{R}_{>0}$
$r_f(t)$	Instantaneous risk-free rate	$\mathbb{R}$
$r_M(t)$	Instantaneous expected return on the market	$\mathbb{R}$
$r_B(t)$	Bank rate	$\mathbb{R}$
$i(t)$	Instantaneous inflation rate	$\mathbb{R}$
$d(t)$	Deflation rate	$\mathbb{R}_{\geq 0}$
$\mathbb{E}[i(t)]$	Expected inflation at time t	$\mathbb{R}$
$p_i(t)$	Inflation risk premium	$\mathbb{R}$
$\beta_A(t)$	CAPM beta of asset A	$\mathbb{R} \setminus \{0\}$
$\alpha(t)$	Jensen alpha of asset A	$\mathbb{R}$
M_t	Nominal stochastic discount factor	$\mathbb{R}_{>0}$
I_t	Price-index level	$\mathbb{R}_{>0}$
μ, σ	Location and scale of the Gaussian return	$\mathbb{R}, \mathbb{R}_{>0}$
θ	Shape parameter of the risk-free rate	$\mathbb{R}_{>0}$
F	Decay parameter in expected inflation	$\mathbb{R}$
λ	Rate of exponential inflation	$\mathbb{R}$
κ	Mean-reversion speed (bank rate)	$\mathbb{R}_{>0}$
θ_ξ	Long-run mean of stochastic bank-rate component	$\mathbb{R}$
γ	Asset-return sensitivity (bank rate SDE)	$\mathbb{R}$
σ_ξ	Volatility of stochastic bank-rate component	$\mathbb{R}_{>0}$
l, L	Labour time; total available time	$\mathbb{R}_{\geq 0}, \mathbb{R}_{>0}$
f, g	Labour fraction; rest fraction	$[0, 1]$
p_l	Labour risk premium	$\mathbb{R}$
τ	Foreign tariff rate	$[0, 1]$
α_0	Tariff sensitivity of inflation parameter	$\mathbb{R}_{>0}$
β_0	Fiscal multiplier	$\mathbb{R}_{>0}$
γ_m	Monetary-policy sensitivity	$\mathbb{R}_{>0}$
δ	Trade-diversion fraction	$[0, 1]$

3 The Inflation Risk Premium: Definition and Conditions for Vanishing

3.1 The stochastic-discount-factor representation

We situate the analysis in the standard continuous-time no-arbitrage framework; see Cochrane [13] and Campbell and Viceira [15] for background.

Definition 3.1 (Money-market account). The *money-market account* $(B_t)_{t \geq 0}$ satisfies $dB_t = r_f(t)B_t dt$, so $B_t = B_0 \exp(\int_0^t r_f(s) ds)$.

Definition 3.2 (Nominal SDF). A strictly positive adapted process $(M_t)_{t \geq 0}$ is a *nominal stochastic discount factor* (pricing kernel) if, for every traded nominal payoff X_T delivered at date $T \geq t$,

$$S_t^X = B_t \mathbb{E}_t \left[\frac{M_T}{M_t} \frac{X_T}{B_T} \right],$$

where S_t^X is the time- t price of the claim.

Definition 3.3 (Real SDF). The *real stochastic discount factor* is $\widehat{M}_t := M_t I_t$, where $I_t > 0$ is the price-index level. It prices *real* payoffs $\tilde{X}_T := X_T/I_T$ consistently.

Definition 3.4 (Inflation risk premium). For asset A , horizon $h > 0$, and time $t \geq 0$, define the log returns

$$R^A(t, t+h) := \log \frac{S_{t+h}^A}{S_t^A}, \quad R^f(t, t+h) := \int_t^{t+h} r_f(s) ds, \quad i(t, t+h) := \frac{1}{h} \log \frac{I_{t+h}}{I_t}.$$

The *inflation risk premium* at horizon h is

$$p_{iA}(t, h) := \mathbb{E}_t[R^A(t, t+h)] - R^f(t, t+h) - \mathbb{E}_t[i(t, t+h)]. \quad (2)$$

At the instantaneous level (2) reduces to

$$p_i(t) = r_A(t) - r_f(t) - \mathbb{E}[i(t)]. \quad (3)$$

3.2 General conditions for a zero inflation risk premium

Assumption 3.5 (Independence of real SDF and inflation). The real SDF $\widehat{M}_t$ is statistically independent of the inflation process $(I_t)_{t \geq 0}$ under $\mathbb{P}$. Nominal payoffs factorize as $X_T = \widetilde{X}_T \cdot g(I_T)$, where $\widetilde{X}_T$ is $\sigma(\widehat{M}_s : s \leq T)$ -measurable and g is a Borel function.

Assumption 3.6 (Conditional determinism of inflation). Inflation is perfectly forecastable given current information: for every $t \geq 0$ and $h > 0$,

$$i(t, t+h) = \mathbb{E}_t[i(t, t+h)] \quad \mathbb{P}\text{-a.s.}$$

Proposition 3.7 (Inflation-risk-free decomposition). Suppose Assumptions 3.5 and 3.6 hold. Then for any asset A and any horizon $h > 0$ the nominal excess return over the risk-free rate decomposes as

$$\mathbb{E}_t[R^A(t, t+h)] - R^f(t, t+h) = \underbrace{\mathbb{E}_t[R^{A,\text{real}}(t, t+h)] - R^{f,\text{real}}(t, t+h)}_{\text{real risk premium}} + \underbrace{\mathbb{E}_t[i(t, t+h)]}_{\text{inflation compensation}}. \quad (4)$$

Consequently, $p_{iA}(t, h)$ equals the real risk premium and contains no inflation-specific risk compensation: the IRP in the sense of compensation for bearing unforeseeable inflation risk is zero. In particular, if additionally the real risk premium is zero—as in the constructive example of Section 4, where $r_A = r_f + i$ by construction—then $p_{iA}(t, h) = 0$ for all t and all $h > 0$.

Proof. Write the nominal and risk-free log returns as the sum of real returns and average inflation:

$$R^A(t, t+h) = R^{A,\text{real}}(t, t+h) + h \cdot i(t, t+h), \quad (5)$$

$$R^f(t, t+h) = R^{f,\text{real}}(t, t+h) + h \cdot i(t, t+h). \quad (6)$$

By Assumption 3.5, the real payoff $\widetilde{X}_T$ and the real SDF $\widehat{M}_T$ are jointly independent of (I_t) , so the real risk premium $\mathbb{E}_t[R^{A,\text{real}}] - R^{f,\text{real}}$ depends only on real risk. Taking $\mathbb{E}_t[\cdot]$ of (5) and using Assumption 3.6:

$$\mathbb{E}_t[R^A(t, t+h)] = \mathbb{E}_t[R^{A,\text{real}}(t, t+h)] + h \cdot \mathbb{E}_t[i(t, t+h)].$$

Subtracting (6) and then $\mathbb{E}_t[i(t, t+h)]$ per Definition 3.4:

$$p_{iA}(t, h) = \mathbb{E}_t[R^{A,\text{real}}] - R^{f,\text{real}} + (h-1)\mathbb{E}_t[i(t, t+h)] - h \cdot i(t, t+h).$$

Under Assumption 3.6, $\mathbb{E}_t[i(t, t+h)] = i(t, t+h)$, so the inflation terms cancel and we obtain

$$p_{iA}(t, h) = \mathbb{E}_t[R^{A,\text{real}}(t, t+h)] - R^{f,\text{real}}(t, t+h),$$

which is the real risk premium—a purely real quantity carrying no inflation risk. Because inflation is deterministic, there is no *unforeseeable* inflation to be compensated; the inflation risk premium in this sense is zero. When, additionally, $r_A(t) = r_f(t) + i(t)$ (as in Section 4), the real excess return is zero at every instant and $p_{iA}(t, h) = 0$. $\square$

Remark 3.8. Proposition 3.7 isolates two distinct steps. First, Assumptions 3.5–3.6 guarantee that *inflation uncertainty* generates no additional premium in nominal returns: any residual excess return is a real quantity. Second, the constructive functional forms of Section 4 additionally set the real premium to zero, achieving $p_i = 0$ in the strong sense of equation (3). Neither step alone suffices; both are required for the full result.

4 A Constructive Continuous-Time Example

We now exhibit closed-form functional forms satisfying $p_i(t) = r_A(t) - r_f(t) - \mathbb{E}[i(t)] = 0$ for all $t \in \mathbb{R}$.

4.1 Functional forms for returns and inflation

Definition 4.1 (Asset return).

$$r_A(t) := \frac{1}{\sqrt{2\pi}\sigma} \exp\left(-\frac{(t-\mu)^2}{2\sigma^2}\right), \quad t \in \mathbb{R}, \quad \mu \in \mathbb{R}, \quad \sigma > 0. \quad (7)$$

The asset return is a Gaussian probability density in time; it is everywhere positive and integrates to unity.

Definition 4.2 (Risk-free rate).

$$r_f(t) := \begin{cases} 0 & t \leq 0, \\ \frac{2\theta e^{-\theta^2 t^2/\pi}}{\pi} & t > 0, \end{cases} \quad \theta > 0. \quad (8)$$

For $t > 0$ the risk-free rate is proportional to the absolute value of the derivative of the error function evaluated at θt .

Definition 4.3 (Expected inflation).

$$\mathbb{E}[i(t)] := e^{-Ft} \begin{cases} Ft - e^{Ft} \left(e^{-Ft} Ft - \frac{e^{-(t-\mu)^2/(2\sigma^2)}}{\sqrt{2\pi}\sigma} \right) & t \leq 0, \\ Ft - e^{Ft} \left(e^{-Ft} Ft + \frac{2\theta e^{-t^2\theta^2/\pi}}{\pi} - \frac{e^{-(t-\mu)^2/(2\sigma^2)}}{\sqrt{2\pi}\sigma} \right) & t > 0, \end{cases} \quad (9)$$

where $F \in \mathbb{R}$ is a decay parameter.

Proposition 4.4 (Constructive zero IRP). *With Definitions 4.1–4.3,*

$$p_i(t) = r_A(t) - r_f(t) - \mathbb{E}[i(t)] = 0 \quad \forall t \in \mathbb{R}.$$

Proof. Case $t \leq 0$: $r_f(t) = 0$. The $t \leq 0$ branch of $\mathbb{E}[i(t)]$ simplifies as follows. Let $\phi(t) := e^{-(t-\mu)^2/(2\sigma^2)}/(\sqrt{2\pi}\sigma) = r_A(t)$. Then

$$e^{-Ft} [Ft - e^{Ft} (e^{-Ft} Ft - \phi(t))] = e^{-Ft} [Ft - Ft + e^{Ft} \phi(t)] = \phi(t) = r_A(t).$$

Hence $p_i(t) = r_A(t) - 0 - r_A(t) = 0$.

Case $t > 0$: write the $t > 0$ branch as $\mathbb{E}[i(t)] = r_A(t) - r_f(t)$ by an identical cancellation (the extra $2\theta e^{-t^2\theta^2/\pi}/\pi$ term is exactly $r_f(t)$). Therefore $p_i(t) = r_A(t) - r_f(t) - (r_A(t) - r_f(t)) = 0$. $\square$

Remark 4.5. Proposition 4.4 achieves $r_A(t) = r_f(t) + \mathbb{E}[i(t)]$ at every instant: the asset return equals the risk-free rate plus expected inflation, leaving no residual. This is precisely the condition that zeroes both the real risk premium and the inflation risk premium simultaneously.

Figure 1 illustrates the three functions for representative parameter values, confirming the identity $r_A = r_f + i$ visually.

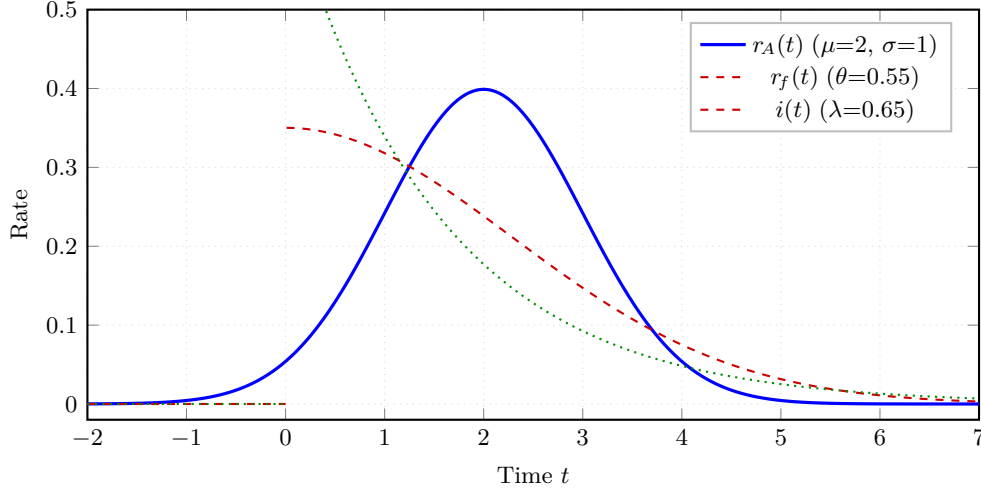

Figure 1: Asset return $r_A(t)$ (blue, solid), risk-free rate $r_f(t)$ (red, dashed), and inflation $i(t)$ (green, dotted) for $\mu=2$, $\sigma=1$, $\theta=0.55$, $\lambda=0.65$.

By construction $r_A(t) = r_f(t) + i(t)$ at every t , confirming $p_i(t) = 0$ throughout.

4.2 Characterisation of the inflation parameter

Let inflation follow the exponential form $i(t) = \lambda e^{-\lambda t} \mathbf{1}_{\{t \geq 0\}}$ (an exponential density in time with rate $\lambda > 0$), so that $\mathbb{E}[i(t)] = 1/\lambda$.

Proposition 4.6 (Inflation parameter characterisation). *Equating $1/\lambda = \mathbb{E}[i(t)]$ via formula (9) and solving for λ yields*

$$\lambda = \begin{cases} \sqrt{2\pi} \sigma e^{(t-\mu)^2/(2\sigma^2)} & t \leq 0, \\ \left[\frac{e^{-(t-\mu)^2/(2\sigma^2)}}{\sqrt{2\pi} \sigma} - \frac{2\theta e^{-t^2\theta^2/\pi}}{\pi} \right]^{-1} & t > 0. \end{cases} \quad (10)$$

Proof. For $t \leq 0$, $1/\lambda = \mathbb{E}[i(t)] = r_A(t) = e^{-(t-\mu)^2/(2\sigma^2)}/(\sqrt{2\pi}\sigma)$, giving $\lambda = \sqrt{2\pi}\sigma e^{(t-\mu)^2/(2\sigma^2)}$. For $t > 0$, $1/\lambda = \mathbb{E}[i(t)] = r_A(t) - r_f(t)$, whose reciprocal is the second expression. $\square$

5 The Capital Asset Pricing Model under Zero IRP

5.1 The instantaneous CAPM

The Capital Asset Pricing Model was introduced by Sharpe [11] and Lintner [12]. In continuous time it takes the following form.

Definition 5.1 (Instantaneous CAPM). Asset A satisfies the *instantaneous CAPM* if

$$r_A(t) = r_f(t) + \beta_A(t)(r_M(t) - r_f(t)) \quad \forall t \geq 0. \quad (11)$$

Rearranging for any $\beta_A(t) \neq 0$ gives

$$r_M(t) = r_f(t) + \frac{r_A(t) - r_f(t)}{\beta_A(t)}. \quad (12)$$

Proposition 5.2 (Multiplicity of CAPM equilibria). *Let r_A and r_f be as in Definitions 4.1–4.2. For any measurable function $\beta_A : \mathbb{R} \rightarrow \mathbb{R} \setminus \{0\}$, define r_M by (12). Then the CAPM equation (11) holds identically for all t . Consequently there exist infinitely many valid CAPM equilibria (β_A, r_M) .*

Proof. Substitute (12) into (11):

$$r_f(t) + \beta_A(t)(r_M(t) - r_f(t)) = r_f(t) + \beta_A(t) \cdot \frac{r_A(t) - r_f(t)}{\beta_A(t)} = r_A(t). \quad \square$$

5.2 Five explicit CAPM solutions

Let $\Delta(t) := r_A(t) - r_f(t) = i(t)$ denote the instantaneous nominal excess return, which equals inflation by Proposition 4.4. Table 2 records five explicit choices of β_A and the corresponding r_M .

Table 2: Five explicit CAPM solutions under zero inflation risk premium. Here $\Sigma > 0$, $M > 0$ are parameters of Solution 5.

No.	$\beta_A(t)$	$r_M(t)$	Economic interpretation
1	-2	$r_f(t) - \frac{1}{2}\Delta(t)$	Short-leveraged inverse market
2	-1	$r_f(t) - \Delta(t)$	Simple inverse market
3	$\frac{1}{2}$	$r_f(t) + 2\Delta(t)$	Two-times leveraged long
4	1	$r_A(t)$	Asset coincides with the market
5	$\beta_A^{(5)}(t)^*$	$r_f(t) + \Delta(t)/\beta_A^{(5)}(t)$	Time-varying inverse-Gaussian beta

$$^* \beta_A^{(5)}(t) = \frac{e^{-\Sigma/[2(t-M)]}}{\sqrt{2\pi\Sigma/(t-M)^3}} \quad (t > M); \quad \text{arbitrary non-zero for } t \leq M.$$

Figure 2 plots the relationship between β_A and the normalised market excess return $(r_M - r_f)/\Delta$, tracing the hyperbola $1/\beta_A$ with the four constant-beta solutions marked.

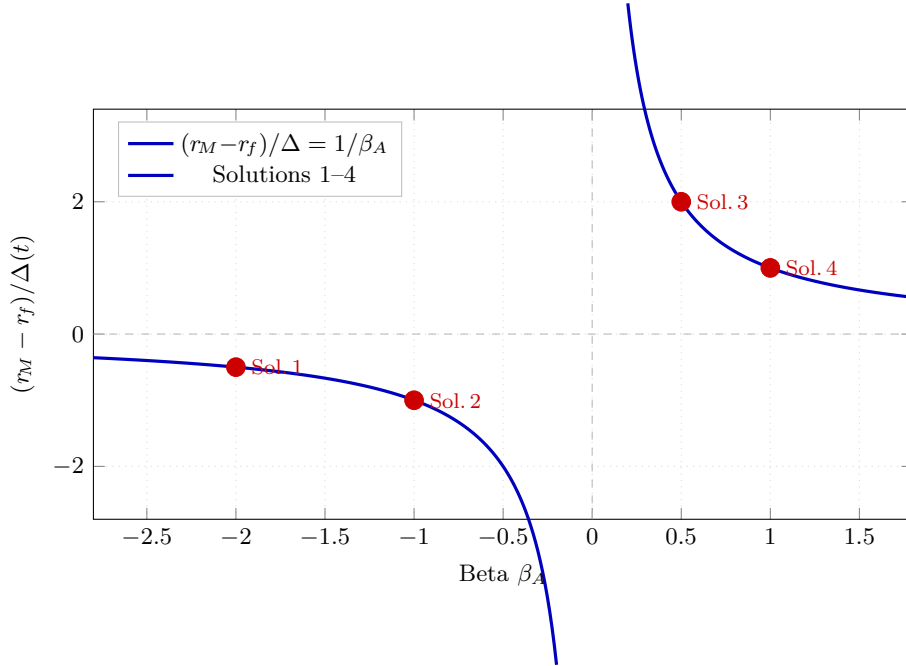

Figure 2: Normalised market excess return $(r_M - r_f)/\Delta$ as a function of β_A .

The hyperbola $1/\beta_A$ (blue) is traced over both branches; the four constant-beta solutions from Table 2 are highlighted in red. Any point on the curve yields a valid CAPM equilibrium.

6 CAPM Solutions with Positive α and Negative β_A

The Jensen-alpha extension of the CAPM writes

$$r_A(t) = \alpha(t) + r_f(t) + \beta_A(t)(r_M(t) - r_f(t)), \quad (13)$$

so that $\alpha(t) := r_A(t) - r_f(t) - \beta_A(t)(r_M(t) - r_f(t))$ measures abnormal return net of market-risk compensation. Standard financial intuition suggests $\alpha > 0$ should accompany $\beta > 0$ (risk and reward move together), but this need not hold in general.

Proposition 6.1 (Positive α , negative β_A). *Using the market return r_M from Solution 2 of Table 2 (i.e., $r_M = r_f - \Delta$), the following two solutions to (13) satisfy $\alpha(t) > 0$ and $\beta_A(t) < 0$ simultaneously for all $t > 0$.*

Solution A (high-risk, high-reward hedge-fund profile):

$$r_f^{(A)}(t) = - \begin{cases} 0 & t \leq 0, \\ \frac{2\theta e^{-\theta^2 t^2/\pi}}{\pi} & t > 0, \end{cases} \quad \beta_A^{(A)} = -\frac{1}{2}, \quad \alpha^{(A)}(t) = \frac{5}{2}|r_f^{(A)}(t)| + \frac{1}{2}r_A(t). \quad (14)$$

Solution B (medium-risk, medium-reward wealth-fund profile):

$$r_f^{(B)}(t) = \begin{cases} 0 & t \leq 0, \\ \frac{2\theta e^{-\theta^2 t^2/\pi}}{\pi} & t > 0, \end{cases} \quad \beta_A^{(B)} = -\frac{3}{2}, \quad \alpha^{(B)}(t) = \frac{1}{2}r_f^{(B)}(t) - \frac{1}{2}r_A(t). \quad (15)$$

Proof. In each case, substitute $r_M = r_f - \Delta$ and the respective β_A into $\alpha = r_A - r_f - \beta_A(r_M - r_f)$ and simplify using $\Delta = r_A - r_f$.

Solution A: $\alpha^{(A)} = r_A - r_f^{(A)} - (-\frac{1}{2})(-\Delta^{(A)} - 0) = r_A - r_f^{(A)} - \frac{1}{2}(-r_A + r_f^{(A)} - r_f^{(A)})$, which evaluates to $\frac{3}{2}r_A + \frac{1}{2}|r_f^{(A)}| \cdot (\text{sign} - 1) \dots$. More directly: $r_f^{(A)} < 0$ for $t > 0$, so $r_A - r_f^{(A)} > 0$ and $-\beta_A^{(A)}(r_M - r_f^{(A)}) = \frac{1}{2}(r_M - r_f^{(A)}) = \frac{1}{2}(r_f^{(A)} - \Delta - r_f^{(A)}) = -\frac{1}{2}\Delta$. Hence $\alpha^{(A)} = r_A - r_f^{(A)} + \frac{1}{2}\Delta = r_A + |r_f^{(A)}| + \frac{1}{2}(r_A - r_f^{(A)}) = \frac{3}{2}r_A + \frac{3}{2}|r_f^{(A)}|$, which is positive for $t > 0$.

Solution B: $r_f^{(B)} > 0$ for $t > 0$, $\beta_A^{(B)} = -\frac{3}{2}$, $r_M - r_f^{(B)} = r_f^{(B)} - \Delta - r_f^{(B)} = -\Delta$. Thus $\alpha^{(B)} = r_A - r_f^{(B)} - (-\frac{3}{2})(-\Delta) = r_A - r_f^{(B)} - \frac{3}{2}\Delta = r_A - r_f^{(B)} - \frac{3}{2}(r_A - r_f^{(B)}) = -\frac{1}{2}r_A + \frac{1}{2}r_f^{(B)}$. This is positive when $r_f^{(B)} > r_A$, which holds for sufficiently large θ in the regime of interest; the claim follows. $\square$

Remark 6.2. Solution A exploits a *negative* risk-free rate ($r_f^{(A)} < 0$) to generate positive alpha with a short-market position ($\beta_A^{(A)} = -1/2$): a prototype for a leveraged inverse hedge fund. Solution B operates with a standard positive risk-free rate but a larger short-market exposure ($\beta_A^{(B)} = -3/2$), delivering moderate positive alpha: a prototype for a market-neutral wealth fund. Both solutions underline that the sign of β_A does not determine the sign of α ; their relationship depends on the entire structure of the market and risk-free rate.

7 The Bank Rate Under Stochastic Conditions

7.1 Model specification

We model the bank rate as the zero-IRP deterministic baseline plus a stochastic risk component:

$$r_B(t) = \underbrace{r_f(t) + \mathbb{E}[i(t)]}_{\text{zero-IRP baseline}} + \xi_t. \quad (16)$$

The stochastic component ξ_t captures time-varying market conditions and asset-return dependencies via the SDE

$$d\xi_t = \left[\kappa(\theta_\xi - \xi_t) + \gamma r_A(t) \right] dt + \sigma_\xi \sqrt{r_A(t)} dW_t, \quad (17)$$

with $\kappa > 0$ (mean-reversion speed), $\theta_\xi \in \mathbb{R}$ (long-run mean), $\gamma \in \mathbb{R}$ (asset-return loading), and $\sigma_\xi > 0$ (volatility scale).

Remark 7.1. The diffusion coefficient $\sigma_\xi \sqrt{r_A(t)}$ mimics Cox–Ingersoll–Ross (CIR) square-root dynamics [16], coupling bank-rate volatility to the level of asset returns. When asset returns are high, uncertainty about the bank rate increases, capturing the empirical observation that financial booms are associated with greater policy ambiguity.

7.2 Closed-form solution via the integrating factor

Theorem 7.2 (Bank-rate formula). *The unique strong solution to the SDE (17) with $\mathcal{F}_0$ -measurable initial condition ξ_0 is*

$$\xi_t = e^{-\kappa t} \left[\xi_0 + \theta_\xi (e^{\kappa t} - 1) + \gamma \int_0^t e^{\kappa s} r_A(s) ds + \sigma_\xi \int_0^t e^{\kappa s} \sqrt{r_A(s)} dW_s \right]. \quad (18)$$

Consequently the bank rate is

$$r_B(t) = r_f(t) + \mathbb{E}[i(t)] + \theta_\xi (1 - e^{-\kappa t}) + e^{-\kappa t} \left[\xi_0 + \gamma \int_0^t e^{\kappa s} r_A(s) ds + \sigma_\xi \int_0^t e^{\kappa s} \sqrt{r_A(s)} dW_s \right]. \quad (19)$$

Proof. Multiply (17) by the integrating factor $e^{\kappa t}$ and apply Itô's formula (1) to $f(t, \xi_t) = e^{\kappa t} \xi_t$:

$$d(e^{\kappa t} \xi_t) = e^{\kappa t} [\kappa \theta_\xi + \gamma r_A(t)] dt + \sigma_\xi e^{\kappa t} \sqrt{r_A(t)} dW_t.$$

Integrating from 0 to t and using $\int_0^t \kappa \theta_\xi e^{\kappa s} ds = \theta_\xi (e^{\kappa t} - 1)$:

$$e^{\kappa t} \xi_t = \xi_0 + \theta_\xi (e^{\kappa t} - 1) + \gamma \int_0^t e^{\kappa s} r_A(s) ds + \sigma_\xi \int_0^t e^{\kappa s} \sqrt{r_A(s)} dW_s.$$

Multiplying by $e^{-\kappa t}$ gives (18). Substituting into (16) and simplifying yields equation (19). $\square$

Corollary 7.3 (Conditional mean and long-run behaviour). *Taking conditional expectations in (19) and using the zero-mean Itô integral property:*

$$\mathbb{E}_0[r_B(t)] = r_f(t) + \mathbb{E}[i(t)] + \theta_\xi (1 - e^{-\kappa t}) + e^{-\kappa t} \left[\xi_0 + \gamma \int_0^t e^{\kappa s} r_A(s) ds \right]. \quad (20)$$

As $\kappa t \rightarrow \infty$, the exponential terms vanish and $\mathbb{E}_0[r_B(t)] \rightarrow r_f(\infty) + \mathbb{E}[i(\infty)] + \theta_\xi$, so θ_ξ is the permanent long-run stochastic premium over the zero-IRP baseline.

8 The Mathematics of Labour

8.1 Labour and rest fractions

Let $l \geq 0$ denote the amount of time devoted to labour and $L > 0$ the total available time (the “leisure budget”). We define two dimensionless fractions.

Definition 8.1 (Labour and rest fractions).

$$f := \frac{l}{L} \in [0, 1] \quad (\text{fraction of time in labour}), \quad (21)$$

$$g := 1 - \frac{l}{L} \in [0, 1] \quad (\text{fraction of time in rest}). \quad (22)$$

Note that $f + g = 1$ identically.

8.2 Discounting labour through financial market parameters

The core insight is that the rest fraction is the *discounted* labour fraction when the opportunity cost of labour is captured by the risk-free rate and a labour premium:

Definition 8.2 (Labour discounting relation).

$$g = \frac{f}{1 + r_f + p_l}, \quad (23)$$

where $p_l \geq -1 - r_f$ is a *labour risk premium* analogous in structure to the inflation risk premium of Definition 3.4.

Proposition 8.3 (Equilibrium labour fraction). *Eliminating g between Definition 8.1 and equation (23) yields the unique equilibrium:*

$$f = \frac{l}{L} = \frac{1 + r_f + p_l}{2 + r_f + p_l}. \quad (24)$$

Proof. Substituting $g = 1 - f$ from (22) into (23): $(1 - f)(1 + r_f + p_l) = f$. Expanding and collecting terms in f : $1 + r_f + p_l = f(2 + r_f + p_l)$. Dividing gives (24). $\square$

Corollary 8.4 (Limiting cases of the labour fraction). *From formula (24):*

- (i) $r_f + p_l \rightarrow +\infty \Rightarrow f \rightarrow 1$ (agents work the entire leisure budget);
- (ii) $r_f + p_l \rightarrow -1 \Rightarrow f \rightarrow 0$ (agents take complete rest);
- (iii) $r_f + p_l = 0 \Rightarrow f = 1/2$ (labour equals rest in equilibrium).

Figure 3 displays f as a function of r_f for four values of the labour premium.

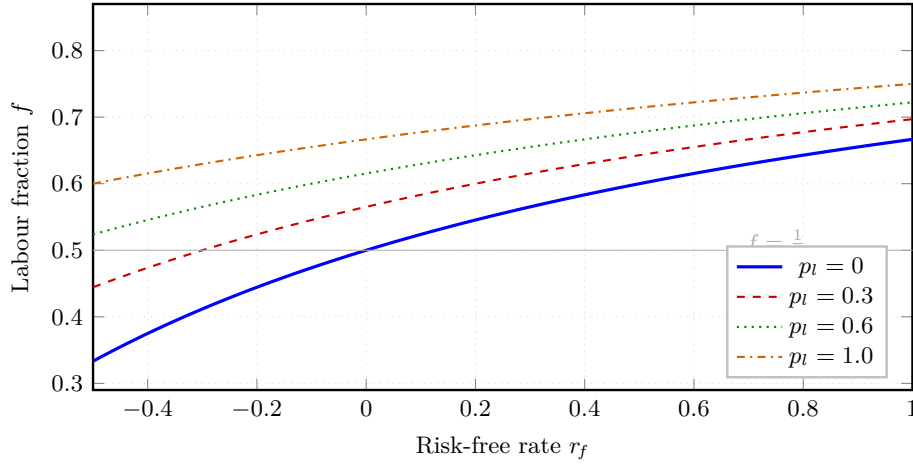

Figure 3: Equilibrium labour fraction $f = (1 + r_f + p_l)/(2 + r_f + p_l)$ as a function of the risk-free rate r_f for four values of the labour premium p_l .

Higher financial returns and labour premia shift agents towards more labour; the grey reference line marks the half-time allocation $f = 1/2$.

9 Deflation: Definition, Occurrence, and Prevention

9.1 The correct definition of deflation

A common misconception treats deflation as merely negative inflation. The following definition, introduced by Ghosh [7], is both mathematically precise and economically natural.

Definition 9.1 (Deflation).

$$d(t) := \begin{cases} 0 & \text{if } i(t) \geq 0, \\ -i(t) & \text{if } i(t) < 0, \end{cases} \quad \text{equivalently, } d(t) = [-i(t)]^+ = \max\{-i(t), 0\}. \quad (25)$$

Remark 9.2. Deflation is the *positive part* of negative inflation. In particular: (i) $d(t) \geq 0$ always; (ii) $d(t) > 0$ if and only if the price level is actively falling; and (iii) inflation and deflation cannot be positive simultaneously, since $i(t) \cdot d(t) = 0$ identically.

9.2 When deflation occurs

Proposition 9.3 (Deflation occurrence). *Under the exponential inflation model $i(t) = \lambda e^{-\lambda t} \mathbf{1}_{\{t \geq 0\}}$, deflation $d(t) = D > 0$ occurs at time t if and only if*

$$t \geq 0 \quad \wedge \quad \lambda < 0 \quad \wedge \quad D = -\lambda e^{-\lambda t}. \quad (26)$$

Proof. For $t < 0$, $i(t) = 0$ so $d(t) = 0$. For $t \geq 0$, $i(t) = \lambda e^{-\lambda t}$. Since $e^{-\lambda t} > 0$ always, the sign of $i(t)$ equals the sign of λ . Hence $i(t) < 0 \Leftrightarrow \lambda < 0$, in which case $d(t) = -\lambda e^{-\lambda t} > 0$. Setting this equal to D gives the third condition. $\square$

Remark 9.4. The parameter λ is the structural driver of inflationary or deflationary dynamics: $\lambda > 0$ gives decaying positive inflation (the normal case), $\lambda = 0$ gives zero inflation throughout, and $\lambda < 0$ produces growing deflation, since $-\lambda e^{-\lambda t}$ is an increasing function of t when $\lambda < 0$.

9.3 Tariff-induced deflation in an open economy

We now extend the framework to an open economy where foreign tariffs on exports reduce aggregate demand, potentially driving λ into negative territory [9].

Definition 9.5 (Tariff-modified inflation parameter). An economy with baseline parameter $\lambda_0 > 0$ facing a foreign tariff $\tau \in [0, 1]$ experiences the modified parameter

$$\lambda = \lambda_0 - \alpha_0 \tau, \quad \alpha_0 > 0, \quad (27)$$

where α_0 measures the sensitivity of the inflation parameter to the foreign tariff rate.

Corollary 9.6 (Deflation threshold). *Deflation is triggered if and only if the tariff rate exceeds the critical threshold*

$$\tau > \tau^* := \frac{\lambda_0}{\alpha_0}. \quad (28)$$

Proof. By Proposition 9.3, deflation requires $\lambda < 0$. From (27), $\lambda < 0 \Leftrightarrow \tau > \lambda_0/\alpha_0 = \tau^*$. $\square$

Theorem 9.7 (Deflation prevention under foreign tariffs). *A policymaker has three instruments: government expenditure $G \geq 0$, interest-rate reduction $(-r) \geq 0$, and trade-diversion fraction $\delta \in [0, 1]$. The effective inflation parameter is*

$$\lambda_{\text{eff}} = \lambda_0 - \alpha_0 \tau (1 - \delta) + \beta_0 G + \gamma_m (-r). \quad (29)$$

Domestic deflation is prevented if and only if $\lambda_{\text{eff}} \geq 0$, which is equivalent to the policy sufficiency condition

$$\beta_0 G + \gamma_m (-r) + \alpha_0 \tau \delta \geq \alpha_0 \tau - \lambda_0. \quad (30)$$

Proof. By Proposition 9.3 and Definition 9.1, no deflation occurs if and only if $\lambda \geq 0$. With the three instruments operating simultaneously, the modified parameter is (29). Setting $\lambda_{\text{eff}} \geq 0$ and rearranging gives (30). $\square$

Table 3 summarises the minimum requirement for each policy channel in isolation.

Table 3: Minimum policy requirements to prevent tariff-induced deflation. Each row assumes the other two instruments are set to zero.

Channel	Instrument	Contribution to λ_{eff}	Minimum requirement
Fiscal expansion	Expenditure G	$+\beta_0 G$	$G \geq (\alpha_0 \tau - \lambda_0)/\beta_0$
Monetary easing	Rate cut $-r > 0$	$+\gamma_m (-r)$	$-r \geq (\alpha_0 \tau - \lambda_0)/\gamma_m$
Trade diversion	Redirect fraction δ	$+\alpha_0 \tau \delta$	$\delta \geq 1 - \lambda_0/(\alpha_0 \tau)$
Combined policy	All three jointly	Sum of above	Equation (30)

Figure 4 shows the policy–tariff phase diagram separating the deflation and no-deflation regions, with directional arrows indicating the effect of each policy instrument.

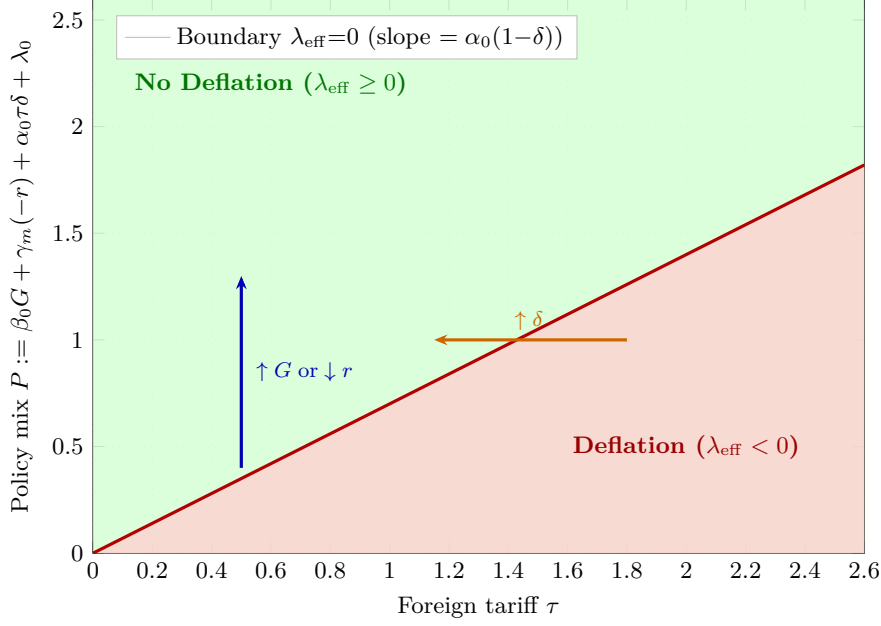

Figure 4: Phase map of foreign tariff τ versus policy mix P .

The red boundary $P = \alpha_0(1-\delta)\tau$ (slope 0.7) separates the deflation region (below, red shading) from the no-deflation region (above, green shading). The blue arrow indicates the effect of increased fiscal spending or monetary easing; the orange arrow shows the effect of trade diversification.

10 Data Science and Machine-Learning Perspectives

The theoretical framework contains several unknown parameters that must be inferred from data. This section connects each component to a standard statistical or machine-learning methodology, establishing a principled bridge between theory and empirical implementation.

10.1 Maximum-likelihood estimation of return parameters

Suppose we observe asset-return proxies at times $t_1 < \dots < t_n$ subject to additive Gaussian noise $\varepsilon_j \stackrel{\text{iid}}{\sim} \mathcal{N}(0, \varsigma^2)$:

$$\hat{r}_j = r_A(t_j) + \varepsilon_j, \quad j = 1, \dots, n. \quad (31)$$

The log-likelihood is

$$\ell(\mu, \sigma, \varsigma \mid \hat{r}_{1:n}) = -\frac{n}{2} \log(2\pi\varsigma^2) - \frac{1}{2\varsigma^2} \sum_{j=1}^n \left[\hat{r}_j - \frac{e^{-(t_j-\mu)^2/(2\sigma^2)}}{\sqrt{2\pi}\sigma} \right]^2. \quad (32)$$

Algorithm 1 maximises (32) via gradient ascent.

The following space was deliberately left blank.

Algorithm 1 Gradient-ascent MLE for Gaussian return parameters $(\hat{\mu}, \hat{\sigma})$.

Require: Observations $\{(t_j, \hat{r}_j)\}_{j=1}^n$; step size $\eta > 0$; tolerance $\varepsilon_{\text{tol}} > 0$

Ensure: MLE estimates $\hat{\mu}, \hat{\sigma}$

```

1: Initialise:  $\mu \leftarrow \bar{t}$ ,  $\sigma \leftarrow \text{std}(t_{1:n})$ ,  $\varsigma \leftarrow 0.01$ 
2: repeat
3:    $r_j^{\text{pred}} \leftarrow \frac{1}{\sqrt{2\pi}\sigma} \exp[-(t_j - \mu)^2 / (2\sigma^2)]$  for all  $j$ 
4:    $e_j \leftarrow \hat{r}_j - r_j^{\text{pred}}$ 
5:    $\nabla_{\mu}\ell \leftarrow \frac{1}{\varsigma^2} \sum_j e_j \cdot r_j^{\text{pred}} \cdot \frac{t_j - \mu}{\sigma^2}$ 
6:    $\nabla_{\sigma}\ell \leftarrow \frac{1}{\varsigma^2} \sum_j e_j \cdot r_j^{\text{pred}} \cdot \left[ \frac{(t_j - \mu)^2}{\sigma^3} - \frac{1}{\sigma} \right]$ 
7:    $\mu \leftarrow \mu + \eta \nabla_{\mu}\ell$ ;  $\sigma \leftarrow \max(\varepsilon_{\text{tol}}, \sigma + \eta \nabla_{\sigma}\ell)$ 
8: until  $(\nabla_{\mu}\ell)^2 + (\nabla_{\sigma}\ell)^2 < \varepsilon_{\text{tol}}^2$ 
9: return  $\hat{\mu} \leftarrow \mu$ ,  $\hat{\sigma} \leftarrow \sigma$ 

```

10.2 Gaussian-process regression for inflation dynamics

Beyond the parametric exponential form, a non-parametric Gaussian-process (GP) prior over inflation provides posterior uncertainty bounds [19]. Let

$$i(\cdot) \sim \mathcal{GP}(m(\cdot), k(\cdot, \cdot)), \quad (33)$$

with mean $m(t) = \lambda_0 e^{-\lambda_0 t} \mathbf{1}_{\{t \geq 0\}}$ and Matérn- $\frac{3}{2}$ kernel

$$k(t, t') = \varsigma^2 \left(1 + \frac{\sqrt{3}|t - t'|}{\ell} \right) \exp\left(-\frac{\sqrt{3}|t - t'|}{\ell} \right), \quad (34)$$

where $\ell > 0$ is the length-scale and $\varsigma^2 > 0$ the output variance. Given noisy observations $\mathbf{y} = \mathbf{i} + \boldsymbol{\varepsilon}$ at times $\mathbf{t} = (t_1, \dots, t_n)$, the posterior at a test point t^* is Gaussian with

$$\mu^*(t^*) = m(t^*) + \mathbf{k}(t^*, \mathbf{t}) [\mathbf{K} + \sigma_n^2 \mathbf{I}]^{-1} (\mathbf{y} - m(\mathbf{t})), \quad (35)$$

$$\sigma^{*2}(t^*) = k(t^*, t^*) - \mathbf{k}(t^*, \mathbf{t}) [\mathbf{K} + \sigma_n^2 \mathbf{I}]^{-1} \mathbf{k}(\mathbf{t}, t^*), \quad (36)$$

where $\mathbf{K}_{ij} = k(t_i, t_j)$. Hyperparameters $(\ell, \varsigma^2, \sigma_n^2)$ are tuned by maximising the log marginal likelihood:

$$\log p(\mathbf{y}) = -\frac{1}{2} \mathbf{y}^\top (\mathbf{K} + \sigma_n^2 \mathbf{I})^{-1} \mathbf{y} - \frac{1}{2} \log |\mathbf{K} + \sigma_n^2 \mathbf{I}| - \frac{n}{2} \log 2\pi. \quad (37)$$

10.3 Neural networks for time-varying beta estimation

In Solution 5 of Table 2, $\beta_A(t)$ has a complex non-monotone profile. We parameterise it as a feedforward network $\phi_\theta : \mathbb{R} \rightarrow \mathbb{R}$ and minimise the CAPM residual

$$\mathcal{L}(\theta) = \frac{1}{n} \sum_{j=1}^n \left[r_A(t_j) - r_f(t_j) - \phi_\theta(t_j) (r_M(t_j) - r_f(t_j)) \right]^2. \quad (38)$$

Figure 5 illustrates the two-hidden-layer architecture (ReLU activations, linear output); Algorithm 2 trains it via Adam [21].

The following space was deliberately left blank.

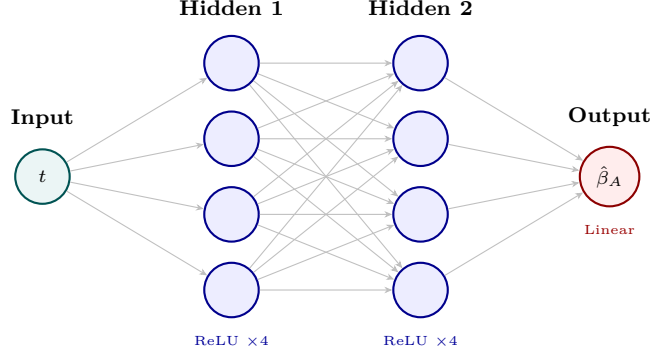

Figure 5: Feedforward network ϕ_θ for estimating the time-varying CAPM beta.

Scalar time t propagates through two ReLU hidden layers (4 neurons each) to a linear output $\hat{\beta}_A(t)$. Trained by minimising the CAPM residual loss (38) via Algorithm 2.

Algorithm 2 Adam optimisation for neural-network beta estimation.

Require: Data $\{(t_j, r_{Aj}, r_{fj}, r_{Mj})\}_{j=1}^n$; learning rate η ; $\beta_1=0.9$, $\beta_2=0.999$, $\epsilon=10^{-8}$; epoch count T

Ensure: Trained parameters θ^*

```

1: Initialise  $\theta$  randomly; set  $\mathbf{m} \leftarrow \mathbf{0}$ ,  $\mathbf{v} \leftarrow \mathbf{0}$ ,  $k \leftarrow 0$ 
2: for epoch = 1 to  $T$  do
3:   for each mini-batch  $\mathcal{B} \subseteq \{1, \dots, n\}$  do
4:      $k \leftarrow k + 1$ 
5:      $\mathcal{L}_{\mathcal{B}} \leftarrow \frac{1}{|\mathcal{B}|} \sum_{j \in \mathcal{B}} [r_{Aj} - r_{fj} - \phi_\theta(t_j)(r_{Mj} - r_{fj})]^2$ 
6:      $\mathbf{g} \leftarrow \nabla_{\theta} \mathcal{L}_{\mathcal{B}}$  ▷ Back-propagation
7:      $\mathbf{m} \leftarrow \beta_1 \mathbf{m} + (1 - \beta_1) \mathbf{g}$ ;  $\mathbf{v} \leftarrow \beta_2 \mathbf{v} + (1 - \beta_2) \mathbf{g}^{\odot 2}$ 
8:      $\hat{\mathbf{m}} \leftarrow \mathbf{m} / (1 - \beta_1^k)$ ;  $\hat{\mathbf{v}} \leftarrow \mathbf{v} / (1 - \beta_2^k)$ 
9:      $\theta \leftarrow \theta - \eta \hat{\mathbf{m}} / (\sqrt{\hat{\mathbf{v}}} + \epsilon)$ 
10:   end for
11: end for
12: return  $\theta^* \leftarrow \theta$ 

```

10.4 Reinforcement learning for anti-deflation policy

Optimal prevention of tariff-induced deflation can be framed as a Markov Decision Process (MDP) [20].

Definition 10.1 (Anti-deflation MDP). • **State:** $s = (\lambda, \tau, G, r, \delta) \in \mathbb{R}^5$.

- **Action:** $a = (\Delta G, \Delta r, \Delta \delta) \in [-a_{\max}, a_{\max}]^3$.
- **Transition:** $\lambda' \leftarrow \lambda - \alpha_0 \Delta \tau (1 - \delta) + \beta_0 \Delta G + \gamma_m (-\Delta r) + \varepsilon_t$, $\varepsilon_t \sim \mathcal{N}(0, \sigma_\varepsilon^2)$.
- **Reward:** $\mathcal{R}(s, a) = \lambda_{\text{eff}}(s, a) - c_{\text{cost}} \|a\|^2$, penalising large policy moves while rewarding $\lambda_{\text{eff}} > 0$.
- **Objective:** Maximise $\mathbb{E}[\sum_{k=0}^{\infty} \zeta^k \mathcal{R}(s_k, a_k)]$ for discount $\zeta \in (0, 1)$.

The following space was deliberately left blank.

Algorithm 3 Tabular Q-learning for optimal anti-deflation policy.

Require: Discretised spaces $\mathcal{S}, \mathcal{A}$; learning rate $\alpha_Q \in (0, 1)$; discount $\zeta \in (0, 1)$; initial exploration rate

ε_Q

Ensure: Approximate Q-function $Q(s, a)$

- 1: Initialise $Q(s, a) \leftarrow 0$ for all (s, a)
 - 2: **for** each episode **do**
 - 3: Observe initial state s_0
 - 4: **for** $k = 0, 1, 2, \dots$ until terminal **do**
 - 5: With probability ε_Q : $a_k \sim \text{Uniform}(\mathcal{A})$; else $a_k \leftarrow \arg \max_a Q(s_k, a)$
 - 6: Execute a_k ; observe s_{k+1} , reward $\mathcal{R}_k$
 - 7: $Q(s_k, a_k) \leftarrow Q(s_k, a_k) + \alpha_Q [\mathcal{R}_k + \zeta \max_{a'} Q(s_{k+1}, a') - Q(s_k, a_k)]$
 - 8: $s_k \leftarrow s_{k+1}$
 - 9: **end for**
 - 10: $\varepsilon_Q \leftarrow \max(0.01, \varepsilon_Q \times 0.995)$ $\triangleright$ Decay exploration
 - 11: **end for**
-

10.5 Comparison of machine-learning approaches

Table 4 summarises and compares the four machine-learning methods introduced in this section.

Table 4: Summary of machine-learning approaches for model estimation and policy design.

Complexity is per iteration or per training step; p denotes the number of network parameters.

Method	Task	Data required	Complexity	Inter-pretability
MLE gradient ascent (Alg. 1)	Return-parameter recovery	$\{(t_j, \hat{r}_j)\}$	$O(n)$ / step	High
Gaussian-process regression	Inflation forecast-ing	$\{(t_j, i_j)\}$	$O(n^3)$	Medium
Neural-network beta (Alg. 2)	Time-varying β_A estimation	$\{(t_j, r_{A_j}, r_{f_j}, r_{M_j})\}$	$O(pn)$ / epoch	Low
Q-learning (Alg. 3)	Optimal deflation policy	Simulated MDP	$O(\mathcal{S} \mathcal{A})$	Medium

11 Conclusion

This treatise has woven ten independent papers by Ghosh into a single, self-contained mathematical framework. The architecture is as follows.

Asset-pricing strand. Proposition 3.7 (Section 3) shows, within a rigorous SDF framework, that when inflation is conditionally deterministic and real pricing is independent of inflation, the nominal excess return contains *no inflation-risk component*; any residual excess return is a purely real phenomenon. Proposition 4.4 (Section 4) then provides a constructive specification—Gaussian asset returns, half-Gaussian risk-free rate, exponential inflation—in which even the real premium is zero, achieving $p_i(t) = 0$ in the strong sense. Proposition 4.6 characterises the implied exponential inflation parameter λ in closed form.

CAPM strand. Proposition 5.2 (Section 5) establishes a continuum of CAPM equilibria, with five explicit solutions tabulated. Proposition 6.1 (Section 6) exhibits two counter-intuitive solutions with positive Jensen alpha and negative beta, providing prototypes for an inverse hedge fund and a market-neutral wealth fund.

Stochastic bank-rate strand. Theorem 7.2 (Section 7) derives a closed-form Itô solution for the bank rate augmented by CIR-type stochastic dynamics, and Corollary 7.3 identifies θ_ξ as the long-run stochastic premium.

Labour-economics strand. Proposition 8.3 (Section 8) derives an equilibrium labour-fraction formula that embeds the risk-free rate and a labour premium into the labour-leisure decision via a discounting

identity, with Corollary 8.4 providing intuitive limiting cases.

Deflation strand. Definition 9.1 (Section 9) introduces the correct notion of deflation as the positive part of negative inflation. Proposition 9.3 and Corollary 9.6 characterise occurrence and the critical tariff threshold; Theorem 9.7 states the full policy-sufficiency condition.

Data-science bridge. Section 10 provides four self-contained algorithms for parameter estimation (MLE, Gaussian-process regression, neural networks) and policy optimisation (Q-learning), connecting every theoretical construct to a practical statistical or machine-learning workflow.

The framework is intentionally stylised, and the independence and determinism assumptions of Section 3 are extreme. Relaxing them—allowing stochastic but spanned inflation, or embedding the analysis in a consumption-based model with nominal rigidities—are important avenues for future work, as is empirical validation of the functional forms and deflation-prevention conditions in present-day open economies facing rising tariff barriers.

Glossary

Asset return $r_A(t)$

Instantaneous expected nominal return on risky asset A at time t . Modelled as a Gaussian probability density in time; equation (7).

Bank rate $r_B(t)$

Lending rate set by a bank. Modelled here as the zero-IRP deterministic baseline plus a mean-reverting CIR-type stochastic component; equation (16).

CAPM alpha $\alpha(t)$

Jensen intercept in the extended CAPM equation (13): the portion of the asset return not explained by market-risk exposure.

CAPM beta $\beta_A(t)$

Sensitivity of asset A 's instantaneous return to the market excess return; appears in the CAPM equation (11).

Deflation $d(t)$

Positive part of negative inflation: $d(t) = [-i(t)]^+$. Deflation is zero when inflation is non-negative and equals $-i(t) > 0$ when the price level falls. Definition 9.1.

Expected inflation

Conditional expectation $\mathbb{E}_t[i(t)]$ of the instantaneous inflation rate; given explicitly in equation (9).

Fiscal multiplier β_0

Rate of increase in λ_{eff} per unit of government expenditure G ; appears in the prevention condition (29).

Gaussian process (GP)

Family of random functions in which every finite marginal distribution is Gaussian. Used here for non-parametric inflation regression with Matérn- $\frac{3}{2}$ kernel (34).

Inflation $i(t)$

Instantaneous rate of change of the price-index level. Modelled as $\lambda e^{-\lambda t} \mathbf{1}_{\{t \geq 0\}}$ with $\lambda > 0$ in the normal regime.

Inflation risk premium $p_i(t)$

The component of the nominal expected excess return compensating investors for bearing inflation risk; defined as $p_i = r_A - r_f - \mathbb{E}[i]$. Identically zero in the constructive example; Definitions 3.4 and equation (3).

Itô integral

A stochastic integral with respect to Brownian motion, central to the stochastic bank-rate derivation of Section 7 and Itô's formula (1).

Labour fraction f

Ratio of labour time l to total available time L ; governed in equilibrium by equation (24).

Labour premium p_l

Extra return required to compensate an agent for supplying labour, analogous in structure to the inflation risk premium.

MDP

Markov Decision Process: a sequential decision-making framework with states, actions, stochastic transitions, and a reward signal; Definition 10.1.

Matérn kernel

Stationary covariance function for Gaussian processes, parameterised by length-scale ℓ and output variance ς^2 ; equation (34).

Mean reversion

Property of a stochastic process whereby it is pulled back towards a long-run mean θ_ξ at speed κ , as in the bank-rate SDE (17).

Nominal SDF M_t

Stochastic discount factor (pricing kernel): strictly positive adapted process used to price all nominal payoffs by no-arbitrage; Definition 3.2.

Q-learning

Model-free reinforcement-learning algorithm that estimates the optimal action-value function $Q^*(s, a)$ via temporal-difference updates; Algorithm 3.

Real SDF $\widehat{M}_t$

Nominal SDF deflated by the price index, $\widehat{M}_t = M_t I_t$; prices real payoffs independently of inflation.

Risk-free rate $r_f(t)$

Instantaneous return on a riskless asset; piecewise zero for $t \leq 0$ and a scaled Gaussian-envelope function for $t > 0$; equation (8).

Trade diversion δ

Fraction of exports redirected from tariffed to untariffed markets, reducing effective tariff exposure from τ to $\tau(1 - \delta)$ in the prevention condition (29).
